Abstract.—Acoustic mate-attracting signals of related sympatric, synchronic species are always distinguishable, but those of related allopatric species sometimes are not, thus suggesting that such signals may evolve to ‘‘reinforce’’ premating species isolation when similar species become sympatric. This hypothesis predicts divergences restricted to regions of sympathy in partially overlapping species, but such ‘‘reproductive character displacement’’ has rarely been confirmed. We report such a case in the acoustic signals of a previously unrecognized 13-year periodical cicada species, Magicicada neotredecim, described here as a new species (see Appendix). Where M. neotredecim overlaps M. tredem decim in the central United States, the dominant male call pitch (frequency) of M. neotredecim increases from approximately 1.4 kHz to 1.7 kHz, whereas that of M. tredem decim remains comparatively stable. The average preferences of female M. neotredecim for call pitch show a similar geographic pattern, changing with the call pitch of conspecific males. Magicicada neotredecim differs from 13-year M. tredem decim in abdomen coloration, mitochondrial DNA, and call pitch, but is not consistently distinguishable from 17-year M. septendecim; thus, like other Magicicada species, M. neotredecim appears most closely related to a geographically adjacent counterpart with the alternative life cycle. Speciation in Magicicada may be facilitated by life-cycle changes that create temporal isolation, and reinforcement could play a role by fostering divergence in premating signals prior to speciation. We present two theories of Magicicada speciation by life-cycle evolution: ‘‘nurse-brood facilitation’’ and ‘‘life-cycle canalization.’’

Key words.—Allochronic isolation, life-cycle evolution, Magicicada, reinforcement, reproductive character displacement, reproductive isolation, speciation.

FIG. 1. Distribution of the seven periodical cicada (Magicicada) species (including one new species described here), summarized from county-level maps in Simon (1988) and from 1993–1998 field surveys in Illinois. The 17-year species are sympatric except in peripheral populations: M. cassini alone inhabits Oklahoma and Texas, whereas only M. septendecim is found in some northern populations (Dybas and Lloyd 1974). Two 13-year species (M. tredecassini and M. tredecula) are sympatric across the entire 13-year range, whereas the remaining 13-year species, M. tredecim and the new species M. neotredecim, overlap only in the central United States. County-level maps overestimate distribution limits, thus the overlap between the 13- and 17-year populations is probably exaggerated. The overlap of M. tredecim and M. neotredecim is plotted from recent field surveys (this study; Simon et al. 2000). Characters distinguishing M.-decim species (see text) are noted; the M.-cassini and M.-decula siblings are distinguishable only by life cycle. Call pitch, dominant pitch of male call phrase; mtDNA lineage, types described in Martin and Simon (1990).

Here we report a new 13-year periodical cicada species, Magicicada neotredecim, that shows reproductive character displacement in male call pitch and female call pitch preferences in the central United States, where it overlaps its closest 13-year relative, M. tredecim (Fig. 1). Magicicada neotredecim appears most closely related to a 17-year counterpart, M. septendecim, from which it may have originated by a life-cycle change (see also Martin and Simon 1988, 1990; Simon et al. 2000). These findings allow further refinement of hypotheses of life-cycle evolution and allochronic isolation in Magicicada and suggest a way in which reinforcement of signal differences in sympatry may facilitate speciation in Magicicada.

MATERIALS AND METHODS

Documenting Sympatric 13-Year Magicicada Species with Calls and Morphology

Periodical cicada populations are extremely large; estimates of population density range from 8355 (Maier 1982) to 3,700,000 per hectare (Dybas and Davis 1962). Most populations contain three species, a M.-decim species that produces a narrow band of sound frequencies with a single dominant pitch between 1 kHz and 2 kHz, and M.-cassini and M.-decula species that each produce broad-spectrum sounds above 3 kHz. (For convenience we refer to Magicicada sibling species groups using the following shorthand: M-decim: M. septendecim [17], M. tredecim [13], and M. neotredecim [13]; M-cassini: M. cassini [17] and M. tredecassini [13]; M-decula: M. septendecula [17] and M. tredecula [13].)

While observing 13-year Magicicada in northern Arkansas in 1998, we found choruses (aggregations of singing males) with two peak frequencies in the M.-decim range (ca. 1.1 and 1.7 kHz), suggesting the presence of two M.-decim species, one previously undescribed (Fig. 2, background of Fig. 3). The location of this discovery suggested that the sympatric M.-decim would correspond to two forms of M. tredecim previously described using mitochondrial DNA (mtDNA) and abdomen coloration (amount of orange on the sternites) and...
found to meet along a zone reaching from Arkansas to Indiana (Martin and Simon 1988).

To determine if the sympatric M.-decim call types correspond to these morphs, we recorded the calls of 150 males collected from a mixed chorus and tested for association of call pitch and abdomen color. We collected the males from privately owned woods 0.25 miles south of County Road 62 on County Road 51, at a powerline right-of-way, just outside the northwest boundary of the Harold E. Alexander Wildlife Management Area, Sharp County, Arkansas; we will refer to this location as the “powerline” site.

All recordings were made using a Sony Professional Walkman cassette recorder with a Sony microphone and parabola, or a Sony 8-mm videocassette recorder with built-in microphone. Because an individual male’s calls do not vary significantly in dominant pitch, we isolated one call of each individual for spectral analysis. For each recording, we generated a power spectrum (plot of sound intensity vs. frequency) using Canary 1.1.1 (Cornell Bioacoustics Laboratory, Cornell University, Ithaca, NY) on a Macintosh computer and obtained the dominant pitch. Individual M.-decim calls consist of a 1–3-sec steady-pitch and nearly pure-tone ‘‘main element’’ followed by a quieter 0.5-sec frequency ‘‘downslur’’ ending about 500 Hz lower than the main element pitch (Fig. 2) (Alexander and Moore 1958; Weber et al. 1988). The main element contains most of the sound energy; therefore, chorus recordings are dominated by the main element pitch. We scored the abdomen color of each individually recorded male using the method of Martin and Simon (1988), assigning each male a value from 1 (ca. 50% black) to 4 (all orange).

We tested for an overall relationship between call pitch and abdomen color class using a Kruskal-Wallis test. Because the preliminary chorus recordings suggested two call types

**FIG. 3.** Power spectrum (shaded area) of mixed Magicicada neotredecim and M. tredecim chorus at powerline study site, Sharp County, Arkansas, showing bimodal sound energy distribution with peaks at approximately 1.1 kHz and 1.7 kHz. Accompanying frequency histograms are for male call pitches (black bars) and female average pitch preferences (white bars) of individuals collected at the site. Males were selected at random; females were selected for the playback experiment separately and with some bias toward the rarer species, which constitutes approximately 8% of the population.
with few intermediates (a bimodal distribution of chorus sound energy), we also divided our male sample by an intermediate pitch of 1.4 kHz and tested for a difference in abdomen coloration using a Mann-Whitney test. All statistical analyses were conducted using Systat (vers. 5.2.1, Macintosh version, Systat, Inc., San Francisco, CA).

**Measuring Female Call Pitch Preferences in Sympatry**

Sexually receptive female *Magicicada* produce timed `wing flick` signals in response to conspecific male calls; conspecific males respond to this signal by dropping out of the chorus, approaching the responding female, and beginning late-stage courtship behavior (Cooley 1999). Most such courtships lead to mating in studies using captive cicadas (J. R. Cooley and D. C. Marshall, unpubl. data). We used this signal as an assay of female mating receptivity to determine whether female preference for call pitch was correlated with abdomen color, using 74 M.-decim females collected from the Sharp County, Arkansas, powerline site. Using Sound Edit Pro (Macromedia, San Francisco, CA), we produced 14 pure-tone model calling phrases differing only in dominant pitch (1.0–2.3 kHz main element pitch, in 0.1-kHz increments); models were designed to mimic the form of normal calls (described above), but contained no pulse structure. In previous experiments, we have found that females respond similarly to playbacks of recorded and artificial calls (Cooley 1999). We played the models to individually marked, caged females in both haphazard and ordered sequences using a Macintosh Powerbook computer connected to an amplified portable speaker positioned 25 cm away from the cage (68–75 dB, as determined by a Radio Shack sound level meter with A weighting). The playback experiments were carried out between 1100 h and 1600 h in bright overcast or sunny conditions against an acoustic background of a *Magicicada* chorus located in woods approximately 8 m away and containing all four 13-year species. Females were tested in groups of four, in random order with respect to abdomen coloration; each was exposed to the entire model set from two-to-ten times as time and mortality allowed. About a third (26/74) of the females did not respond to any call; these were dropped from the analysis. This response rate is similar to that observed in studies of 17-year *M. septendecim* females in Virginia and Illinois (Cooley 1999), where only one M.-decim species is known. For each female, we averaged all model call pitches that elicited one or more wing-flick responses to determine the average pitch preference.

We scored female abdomen color using the method described above for males and tested for association between average pitch preference and abdomen color class by a Kruskal-Wallis test. In addition, using the intermediate pitch value (1.4 kHz) observed in the male sample, we divided the female sample in two by average pitch preference and tested for a difference in abdomen coloration using a Mann-Whitney U-test.

**Estimating Species Distributions and Geographic Variation in Calls**

Once we had demonstrated the existence of two sympatric 13-year M.-decim species differing in call pitch, we estimated the species’ distributions and measured geographic variation in dominant chorus pitch using recordings (15–30 sec in duration) taken from 80 locations distributed throughout the 1998 *Magicicada* emergence. The 17- and 13-year life cycle groups each have formed several largely allopatric broods that emerge in different years; the broods are numbered according to year-class, from I to XVII for 17-year cicadas and from XVIII to XXX for 13-year cicadas. There are 12 extant 17-year broods and just three 13-year broods, so many year-classes are empty (see individual brood maps in Simon 1988). The 1998 13-year emergence involved the large brood XIX, which reaches from Maryland to Oklahoma. Recording dates are given in Table 2.

For mixed choruses, we used the relative intensities of the two species-specific M.-decim dominant chorus pitches to estimate relative proportions of the species; these intensities were measured from the power spectrum of each chorus recording. This approach assumes that both species show the same relationship between male abundance and chorus intensity. Because field conditions did not allow direct comparisons of male sound output of the two M.-decim species, we tested the assumption indirectly: In the mixed-species powerline chorus from Sharp County, Arkansas, we compared the distribution of individual call pitches of a random collection of 123 males to the distribution of acoustical energy in the chorus power spectrum, using a Kolmogorov-Smirnov test. The effectiveness of using chorus recordings to estimate M.-decim chorus composition is further improved if the two species do not form mutually exclusive spatial aggregations. To test this assumption, we recorded a continuous chorus sample along a 200 m woods border in the Harold E. Alexander Wildlife Management Area, Sharp County, Arkansas, while pointing the parabola/microphone assembly into the treetops at a 45° angle. We recorded one side while walking in one direction and then recorded the other side while returning. From samples of this recording taken at 7 m intervals, we measured the intensities of the *M. neotredecim* and *M. tredecim* frequency bands from power spectra; this yielded 47 samples because of gaps in the forest on one side (350 m total). If the *M. neotredecim* and *M. neotredecim* and *M. tredecim*...
tredecim at the site were not uniformly distributed with respect to one another on a local scale, we would expect to observe significant variation among locations in the relative intensities of the two species’ chorus bands.

**Additional Tests for Demonstrating Reproductive Character Displacement**

As described below in Results, geographic sampling of choruses revealed an apparent pattern of reproductive character displacement in M. neotredecim call pitch, with more southern populations (those overlapping M. tredecim) exhibiting higher call pitch. Further confirmation of the pattern necessitated additional tests deriving from Waage’s (1979) criteria 1 and 3 (see Introduction).

To determine if female call pitch preferences change geographically with male call pitch in M. neotredecim, a predicted pattern if male call pitch functions in mate recognition, we measured average pitch preferences of 33 M. neotredecim females collected from a woodlot 0.8 miles south of White Heath, Illinois, on Route 1300E (Piatt Co.), beyond the range of M. tredecim. Twelve of these females were responsive during the test; the remainder were discarded. We completed the playback experiments at nearby Lodge Park Forest Preserve against a background chorus containing M. neo- tredecim, M. tredecassini, and M. tredecula. We used a Mann-Whitney U-test to determine if the average pitch preference of the Piatt County females differed from that of the Sharp County, Arkansas, powerline site females. Because of time constraints, we were unable to study allopatric M. tredecim females.

To test the alternative possibility that call pitch variations could be explained as a secondary effect of a north-south cline in male size, we compared the call pitches and body sizes of 61 M. neotredecim and 26 M. tredecim males from sympathy at the Sharp County, Arkansas, powerline site with those of 17 M. neotredecim males collected in Allerton Park, Piatt County, Illinois, where no M. tredecim are present. We used three characters to estimate size: right wing length, thorax width between the wing articulations, and first abdominal sternite width between the sutures that join the sternite to the terga. We conducted pairwise comparisons among populations using Mann-Whitney U-tests. For each population, we tested for associations between size-related traits and call pitch using linear regressions.

**RESULTS**

*Behavioral and Morphological Evidence for Sympatric Magicicada -decim Species*

The Kruskal-Wallis test indicated a strong relationship between male call pitch and abdomen color class at the Sharp County, Arkansas, powerline site (Table 3). Furthermore, the 150 individual male call pitches fell into two distinct groups with no intermediate pitch values from 1.20 kHz to 1.42 kHz (Fig. 3), confirming the bimodal chorus energy distribution observed in chorus recordings. A Mann-Whitney comparison showed that these two groups differed significantly in abdomen coloration (Table 3): Males producing calls with low dominant pitch had the orange abdomen color characteristic of Martin and Simon’s (1988) mtDNA lineage B, now recognized to be the previously described M. tredecim (Alexander and Moore 1962). M.-decim males producing higher-pitch calls had the darker abdomen color of Martin and Simon’s mtDNA lineage A, and constitute a new species here named M. neotredecim (description in Appendix). Among approximately 250 male cicadas observed during our study, we found just four putative intermediates: two high-pitch males with orange abdomens (category 4), one low-pitch male with a darker abdomen (category 2), and one male with an intermediate call (1.43 kHz).

**Female Call Pitch Preferences and Morphology in Sympatry**

Most responding females wing-flicked (WF) to model calls of several different pitches (mean = 6.8 different call pitches, SD = 3.2). The average range of response (highest pitch eliciting WF − lowest pitch eliciting WF) was similar (mean = 7.4, SD = 3.5), because most females responded to a continuous rather than fragmented range of frequencies. There was a strong relationship between average pitch preference and abdomen color (Table 4). The bimodal phenotypic distribution apparent in male M.-decim call pitch appeared in the distribution of average female pitch preferences as well, indicating two classes of females (Fig. 3). When the female sample was divided at the intermediate pitch of 1.4 kHz, the resulting female groups differed in abdomen coloration just as in the male sample: Females responding on average to low-pitch calls (M. tredecim) were significantly more orange than females responding on average to high-pitch calls (M. neotredecim; Table 4).

**Species Distributions and Geographic Variation in Male Calls**

Using chorus recordings to estimate species abundance.— The random sample of individual male calls from the Sharp
TABLE 4. Thirteen-year female M.-decim (see text for species) call pitch preference types are species corresponding to abdomen color morphs identified by Martin and Simon (1988). (A) Kruskal-Wallis test, with pitch preference as dependent variable, indicates overall relationship between pitch preference and abdomen coloration (test statistic = 10.58, $P \leq 0.014$). (B) Dividing the bimodal female M.-decim pitch preference sample (Fig. 3) by an intermediate pitch preference (1.4 kHz) yields two groups differing significantly in abdomen color (Mann-Whitney $U = 317,000$, $P \leq 0.001$).

County, Arkansas, powerline population indicated a strong relationship between relative abundance of the M.-decim species and the distribution of sound energy in the chorus: The standardized histogram of call pitches of individually recorded males was indistinguishable from the standardized quadratic chorus power spectrum (Kolmogorov-Smirnov test, $P > 0.05$; Fig. 3).

Although the proportions of the two M.-decim species vary on a scale of miles (e.g., Fig. 4 inset), the 13-year M.-decim species do not appear to cluster significantly within a location. In the 350-m continuous recording the proportion of M.-decim chorus sound produced by the rarer species (M. neotredecim) remained between 10% and 36% of the total chorus sound output (mean = 19.0%, SD = 6.0, $n = 47$), and the chorus intensities of the two species were not significantly negatively correlated (Pearson coefficient = $-0.229$, $P = 0.121$).

Geographic overlap and reproductive character displacement in male call pitch between M. neotredecim and M. tredecim.—We found M. neotredecim in Missouri, Illinois, western Kentucky, and northern Arkansas (Fig. 4; see also Simon et al. 2000). The southernmost M. neotredecim populations overlap M. tredecim in a zone 50–150 km wide reaching from northern Arkansas into southern Missouri, southern Illinois, and western Kentucky. The remainder of brood XIX contains M. tredecim and not M. neotredecim.

Geographic variation in dominant chorus pitch of M. neotredecim occurs in a pattern of reproductive character displacement (Fig. 5). Magicicada neotredecim choruses have the highest dominant pitch (ca. 1.7 kHz) in sympathy with M. tredecim; in this region individual M. neotredecim males have call pitches as high as 1.9 kHz. North of the overlap zone, M. neotredecim dominant chorus pitch decreases to

![Fig. 4](image-url) Relative proportions of Magicicada neotredecim (black) and M. tredecim (white) estimated from chorus recordings of the 1998 emergence of Magicicada 13-year brood XIX.
there is no overall difference between choruses in sympathy and allopatria with *M. neotredecim* (Table 5).

Most of the chorus samples likely included the calls of hundreds or thousands of males. However, many of the populations from Missouri and Alabama were recorded late in the emergence when comparatively few males remained (Table 2). For these locations, the chances of overlooking a rare species were greater.

**Additional Tests of Reproductive Character Displacement**

Female *M. neotredecim* call pitch preferences change geographically with male call pitch: In sympatry with *M. tredecim*, (powerline site, Sharp Co., AR) female *M. neotredecim* were most responsive to an average pitch of $1.72 \pm 0.15$ kHz ($n = 38$), while in allopatria (Piatt Co., IL) female preference averaged $1.31 \pm 0.10$ kHz ($n = 12$; Mann-Whitney $U = 451$, $P \leq 0.001$). Allopatric *M. neotredecim* also differed significantly ($U = 104$, $P \leq 0.003$) in pitch preference from the Arkansas (powerline site) *M. tredecim* (mean $1.19 \pm 0.06$ kHz, $n = 10$).

*Magicicada tredecim* and *M. neotredecim* in sympatry were significantly different in all size measurements, although the magnitudes of these differences were not as great as those observed in call pitch (Fig. 2). *Magicicada neotredecim* populations from Illinois and Arkansas differed in call pitch but not in size (Fig. 7). We found no significant relationship between call pitch and any measure of body size within species in any population using linear regressions.

**DISCUSSION**

**Call Pitch and 13-year Magicicada-decim Species**

The conclusion that *M. tredecim* and *M. neotredecim* are the 13-year *M.-decim* forms identified by Martin and Simon (1988, 1990) is supported by the correlation of call pitch differences with abdomen coloration differences and by the fact that the species’ distributions within brood XIX as determined using call phenotypes closely match those estimated by Martin and Simon using morphology and mtDNA (Martin and Simon 1988, 1990). The scarcity of call and preference intermediates (Figs. 2, 3) suggests that viable adult hybrids are rare (see also Simon et al. 2000); this could be due to hybrid failure or lack of interbreeding.

Because females of the two 13-year *M.-decim* species were able to distinguish call models varying only in dominant

---

**Table 5.** Sympatric and allopatric *Magicicada neotredecim* populations differ significantly in dominant chorus pitch (Mann-Whitney $U = 21$, $P \leq 0.001$), whereas those of *M. tredecim* do not ($U = 120.5$, $P \leq 0.824$). The comparison is conservative because some apparently allopatric populations of *M. neotredecim* were recorded late in the emergence when cicadas were sparse and rare *M. tredecim* may have been missed.

1 Only two of the 34 allopatric *M. neotredecim* populations have dominant pitch values higher than 1.62 kHz; both are from southern Missouri.
pitch, and because female call pitch preferences correlate with abdomen coloration types, call pitch differences are likely an important cause of species specificity in M.-decim mate recognition. In addition to the dominant pitch, natural calls contain temporal patterns that result from individual tymbal contractions and the buckling of tymbal ribs (Young and Josephson 1983; Weber et al. 1988); our model calls did not contain such patterns. However, differential responses to our model calls demonstrate that such temporal characteristics are not required for mate recognition, and the call pitch differences are unlikely to be explained as secondary effects of differences in tymbal pulse rate. Variations in M. septendecim tymbal contraction rate do not alter dominant call pitch, which may be determined by physical properties of the resonating abdomen and its large air sac (Young and Josephson 1983). Furthermore, we found no relationship between air temperature (which affects tymbal contraction rate) and chorus pitch in 11 recordings taken from the same location at different times (Fig. 8). Little is known of the relative roles of temporal patterning and frequency content in cicada calls in general, although both function in Australian bladder cicadas (Cystosoma; Doolan and Young 1989), each in a different context.

Reproductive Character Displacement in Magicicada neotredecim

The increase of M. neotredecim call pitch in sympatry with M. tredecim (a change of nearly 25%) meets the criteria established by Waage (1979) for reproductive character displacement (see Introduction). The model call playback experiments demonstrate that the difference in 13-year M.-decim call pitch in sympatry likely plays a role in mate recognition, and that the range of variation is perceptible to the species. The fact that allopatric populations of M. neotredecim in Illinois are indistinguishable in call pitch from 17-year M. septendecim (dominant chorus pitch 1.30–1.45 kHz; unpubl. data), the new species’ closest relative (Martin and Simon 1988, 1990), supports the conclusion that the high call pitch of M. neotredecim in the overlap zone is derived. No trends exist in allopatry that can explain the pattern of displacement; rather, the displacement is associated with the zone of sympatry. In Illinois and eastern Missouri, nearly all of the geographic change in dominant chorus pitch occurs in an approximately 50-km zone immediately north of the M. tredecim range limit, and variation among allopatric populations or among sympatric populations is comparatively minor (Fig. 5); the pattern in central Missouri is less striking, however (see below). In addition, the change in call pitch does not appear to be an incidental effect of a latitudinal cline in body size (Fig. 7). Finally, the requirement that the divergence be attributable to reproductive interactions of the species is indirectly supported by the fact that average M. neotredecim and M. tredecim calls in sympatry differ just enough to avoid frequency overlap, with M. neotredecim downslores ending at approximately the dominant call pitch of M. tredecim (Fig. 2).
A potential challenge to the conclusion of reproductive character displacement arises because some central Missouri populations apparently well outside the range of *M. tredecim* have a partially elevated *M. neotredecim* dominant chorus pitch (ca. 1.5 kHz). This pattern could be explained if *M. neotredecim* colonized Missouri from Illinois populations that were themselves adjacent to the range of *M. tredecim* or if undiscovered *M. tredecim* populations exist in Missouri near the locations we sampled. Future surveys should investigate the latter possibility. Because *M. tredecim* appears to reach its northern limits on Mississippi and Wabash lowlands, it may be found only in restricted locations near rivers elsewhere in the northern part of its range.

Also of interest is that the dominant chorus pitch of *M. neotredecim* does not correlate with the relative abundance of the two 13-year *M.-decim* species in mixed populations (linear regression, $r^2 = 0.053$, $P > 0.3$, $n = 21$). This appears to undermine the conclusion that the displacement is attributable to reproductive interactions of the two species (Waage 1979, criterion 4), if the strength of reinforcing selection on one species is expected to depend on the abundance of the other (Howard 1993; Noor 1995). However, the prediction of frequency dependence is not appropriate under some circumstances. Average *M. neotredecim* calls in sympatry are displaced just enough to avoid frequency overlap with *M. tredecim* (Fig. 2), suggesting that reinforcing selection may cease at that point; if only small numbers of *M. tredecim* are necessary to drive this change in *M. neotredecim*, then a correlation between relative abundance and degree of displacement would be detectable only among populations with extremely rare *M. tredecim*. In addition, if conditions influencing the relationship between relative abundance and displace-
ment vary across regions, then the correlation may have been obscured by our combined analysis of all mixed populations; a more local scale of analysis could reveal the expected relationship. The data from southern Illinois (Fig. 5 inset), for example, suggest greater displacement in southern populations where *M. neotredecim* is more rare; however, this possibility will not be resolved without additional data.

*Magicicada neotredecim* call pitch has changed much more than that of *M. tredecim*; such asymmetries are not unusual in cases of reproductive character displacement (e.g., Littlejohn 1965; Littlejohn and Loftus-Hills 1968; Fouquett 1975; Waage 1979; Noor 1995). In general, because the strength of selection on each species depends on factors that can differ between them, symmetrical displacement is probably unlikely (Grant 1972; Howard 1993). Possible explanations in the *Magicicada* case include the following: (1) greater numerical abundance of *M. tredecim* relative to *M. neotredecim* during critical stages of the interaction, perhaps because *M. neotredecim* originally invaded established *M. tredecim* populations and not vice versa; (2) greater *M. tredecim* female selectiveness upon initial contact; (3) greater constraints on the evolution of lower call pitch.

Reinforcement and Speciation

The criteria for reproductive character displacement (sensu Howard 1993) as established by Waage (1979) reflect an expected outcome of natural selection reducing inefficiencies arising from heterospecific sexual interactions; such selection is sometimes referred to generally by the terms “reinforcement” or “reinforcing selection.” In general, the reproductive inefficiencies driving such selection could range from interbreeding with partial hybrid success and limited introgression to interbreeding with complete hybrid failure to simple reproductive interference (e.g., crossmatting with morphological incompatibility or signal interference without crossmatting). Because reinforcing selection can reduce gene flow between populations under certain conditions (Rice and Hostert 1993; Liou and Price 1994), such selection has been considered a process of speciation (Dobzhansky 1940; Blair 1955; Butlin 1995; Kelly and Noor 1996). In accordance with this view, Butlin (1987, 1989) argues for a redefinition of terms: “Reinforcement” should apply only when premating isolation is enhanced despite interbreeding and gene flow, and the term “reproductive character displacement” should refer to the divergence of mate recognition systems when hybrids are sterile. Under this terminology, only reinforcement is a candidate speciation mechanism because speciation is already completed if gene flow is not possible (Butlin 1989).

This approach has two weaknesses. First, reinforcement may be best viewed not as a mechanism of speciation, but instead as a process that only species undergo. Most species definitions reflect a general concept of species as “population-level evolutionary lineages” (de Queiroz 1998); the best evidence (when available) of the distinctiveness of such lineages is their ability to remain distinct and/or diverge even in sympathy. Reinforcement occurs only if, prior to contact, divergence in allopatry or allochrony has caused two populations to accumulate sufficient reproductive incompatibilities; thus, the occurrence of reinforcement is itself evidence that the populations were species (able to remain distinct in sympathy/synchrony) before contact. Therefore, reinforcement is more an effect of speciation than a cause, regardless of whether the populations exchange genes at any point. This view of reinforcement and speciation does not require distinctions based on degree of hybrid failure. Furthermore, this approach is compatible with evidence of widespread natural hybridization (e.g., Grant and Grant 1992; Arnold 1997), which suggests that species status should not be rejected simply on the basis of incomplete hybrid sterility or naturally occurring gene flow.

Second, the new definitions are impractical because neither term can be applied to a given case of reproductive character divergence if the extent of past gene flow between the species is unknown. We do not know if *M. neotredecim* and *M. tredecim* exchanged genes upon first contact. Evidence that hybridization is currently rare or absent does not prove that it did not occur in the past, so additional analysis will not necessarily resolve the question. Therefore, there may be value in retaining a general concept of reinforcement as a process of reproductive character divergence driven by selection against wasteful heterospecific sexual interactions, without assumptions of crossmatting, gene flow, or even relatedness of interactants; the term is used in this manner for the remainder of this paper.

Allochronic Isolation and Life-Cycle Evolution in *Magicicada*

Because 13-year *M. neotredecim* and 17-year *M. septendecim* have parapatric distributions and are consistently distinguishable only in life cycle length, one of these two species likely originated from ancestral populations of the other (Martin and Simon 1988, 1990); the comparatively restricted range of *M. neotredecim* (Fig. 1) and the likely recent nature of its contact and reinforcement with *M. tredecim* are most consistent with recent derivation of *M. neotredecim* from *M. septendecim* (see also Simon et al. 2000). Together, these sibling species differ from 13-year *M. tredecim* in call pitch, abdomen coloration, and mtDNA (estimated 2.6% divergence), suggesting separation from *M. tredecim* 1–2 million years ago (Martin and Simon 1990). If *M. neotredecim* is derived from *M. septendecim*, then reinforcement in *M. neotredecim* has resulted not from contact with the species’ closest relative, as the process is often modeled, but from contact with a more distantly related species.

The periodical cicada complex appears to be an excellent model system for the study of speciation involving allochronic isolation (see also Alexander and Moore 1962; Simon et al. 2000): Every periodical cicada species is most closely related to a congener with the alternative life cycle, and life-cycle changes could partially or completely isolate new forms from parental populations in time (Alexander and Moore 1962). White and Lloyd (1975) found that the life-cycle difference between 13- and 17-year species can be explained by an early four-year developmental dormancy period found only in 17-year cicadas. This finding, combined with observations of apparently facultative four-year accelerations in 17-year populations (e.g., Dybas 1969; Kritsky and Simon
Mutations influencing life-cycle evolution in the overlap zone if they emerge synchronously with the 13-year species. 17-year cicadas (A) mutate (to a') in the overlap zone if they emerge synchronously with the 13-year 'nurse' brood (13 B + 13 C). Success of life-cycle mutants from 17 A is facilitated in the life-cycle overlap zone because 13 B and 13 C provide the rare mutants with numerical protection from predators. Rare life-cycle mutants from 17 B and 17 C are likely to be lost to interspecific hybridization with the similar and abundant 13 B and 13 C. Degree of prior divergence of 13 A and the parent species 17 A will influence the evolutionary outcome (mixture, hybrid zone, or reinforcement) of later contact between 13 A' and 13 A.

Nurse-brood facilitation. Mutations influencing life-cycle length could facilitate evolution of a new *Magicicada* species by allochronic isolation if a process existed by which such founders could escape predation. The observation that broods of different life cycles sometimes overlap under one another in the same woods (Lloyd et al. 1983; Simon 1988) suggests such a mechanism: Life-cycle mutants from one brood could survive if their initial appearance were fortuitously timed with the emergence of a geographically overlapping brood with the same life cycle as the mutants (Fig. 9), which would then remain synchronized with the nurse brood (see also Lloyd and Dybas 1966, Simon et al. 2000). The temporal 'migrants' would have to appear in numbers sufficient to permit them a chance of locating another one as conspecific mates; the need for multiple simultaneous mutants to appear at once may be mitigated by the large size of periodical cicada populations, which can reach 3.7 million per hectare (Dybas and Davis 1962) and by the possibility that a discrete developmental change underlies the life-cycle difference of 13- and 17-year species. Nurse-brood facilitation of life-cycle mutants thus suggests an explanation for the tendency of *Magicicada* to repeatedly evolve species-pairs with the same alternative life cycles (Alexander and Moore 1962).

Temporal migrants are most likely to successfully establish themselves if the nurse brood does not already contain a confusingly similar species; the presence of such a species could result in the new mutants being lost to interspecific hybridization or failed mate location. However, prior reinforcement within a brood could alleviate this difficulty (Fig. 10) by increasing the differences between allopatric forms prior to contact. For example, reinforcement in 13-year *M. neotredecim* has incidentally caused some populations of this species to differ from nearby 17-year *M. septendecim* populations in dominant chorus pitch by approximately 300 Hz. If future 17-year life-cycle mutants from such a call-displaced *M. neotredecim* population coemerge with 17-year cicadas in the life-cycle overlap zone, the preexisting pitch differences might facilitate assortative mating of the new incipient 17-year species (Fig. 10). In this model, reinforcement acts prior to speciation by causing divergence in allopatry that incidentally facilitates successful coexistence upon establishment of sympatry.

Life-cycle shifts and canalization. Observations suggesting that *Magicicada* life-cycle length can be influenced by unusual climatic conditions (Alexander and Moore 1962), sometimes in four-year increments, suggest an alternative mechanism for speciation via life-cycle shift, here termed 'life-cycle canalization.' In this model, first presented by Lloyd and Dybas (1966), the initial isolation facilitating divergence results from the expression of latent phenotypic plasticity (e.g., West-Eberhard 1989); in contrast, under the nurse-brood model the initial isolation of the incipient species derives from intrinsic, genetic changes.

Developmental plasticity could facilitate life-cycle evolution and speciation in *Magicicada* if extreme climatic conditions sometimes induce periodical cicadas to switch life cycle in numbers sufficient to satiate predators and if the conditions persist for generations. Persistence of the extreme conditions would cause continued expression of the new cycle, during which time selection would favor genes that tend to canalize the new phenotype, as long as cicadas expressing the old phenotype fail to satiate predators. Furthermore, if the climate returns to the initial conditions gradually, cana-
lizing selection could lead to the evolution of cicadas that express the new life cycle even under the original conditions (Fig. 11; see Waddington 1953). In addition, if only small numbers of cicadas were triggered to switch life cycle, the mechanism of nurse brood facilitation could operate to shield them from predators, as in the mutation-based model above.

If different *Magicicada* species possess similar life cycle plasticity, a climate shift causing a change in the life cycle of one species could change sympatric species in a similar fashion, resulting in simultaneous, parallel speciation events. Thus, if *M. neotredecim* was formed from populations of *M. septendecim* by canalization of a climate-induced life cycle, we might expect to find that similar undiscovered 13-year *M. cassini* and *M. decula* species coexist with *M. neotredecim*.

APPENDIX

Species Description

Magicicada neotredecim, new species.—Holotype (male): Collected by J. R. Cooley and D. C. Marshall on 18 May 1998 in Sharp County, Arkansas, in a powerline right-of-way on County Rd. 51 approximately 0.25 miles south of County Road 62 (36°15.36′N; 91°27.72′W), outside the Harold E. Alexander Wildlife Management Area. Dominant pitch of male call phrase 1.68 kHz. Deposited at the University of Michigan Museum of Zoology (UMMZ), Ann Arbor, Michigan, with a digital recording of the male’s call. For comparative description see Table 1. Allotype: Collected by Cooley and Marshall on 18 May 1998 at the same location as holotype. Deposited at UMMZ.
